Understanding strongly correlated quantum systems is a central problem in many areas of physics. The collective behavior of interacting particles gives rise to diverse fundamental phenomena such as confinement in quantum chromodynamics, phase transitions, and electron fractionalization in the quantum Hall regime. While such systems typically involve massive particles, optical photons can also interact with each other in a nonlinear medium. In practice, however, such interactions are often very weak. Here we describe a novel technique that allows the creation of a strongly correlated quantum gas of photons using one-dimensional optical systems with tight field confinement and coherent photon trapping techniques. The confinement enables the generation of large, tunable optical nonlinearities via the interaction of photons with a nearby cold atomic gas. In its extreme, we show that a quantum light field can undergo fermionization in such one-dimensional media, which can be probed via standard photon correlation measurements.

The idea of using nonlinear effects to create optical systems with unusual properties has been pursued for several decades, and fascinating advances have made in recent years [1, 2, 3, 4, 5]. The focus of such work has mostly been on systems containing a small number of photons. At the same time, the effects of strong correlations manifest themselves most dramatically in many-body systems, often resulting in new states of matter with properties that are very different from those of the underlying particles. One famous example is the Tonks-Girardeau (TG) regime of interacting bosons in one dimension, in which strong interactions between particles lead to an effective "fermionization" of bosons [6, 7]. This unusual regime has been explored in several condensed matter systems and in recent experiments with ultracold atoms in one dimensional traps [8, 9]. In this article we investigate the feasibility of creating and detecting a TG gas of photons. This system would correspond to nonlinear quantum optics in its extreme, in which individual photons behave as impenetrable particles. In this limit, an optical pulse separates into non-overlapping wavepackets of individual photons, and a "crystal of photons" can be created.

Several papers have recently considered the possibility of phase transitions involving photons, focusing on large systems of coupled optical cavities [10, 11, 12, 13]. The present study extends this important work along two principal directions. First, while dramatic progress has been achieved in controlling individual atoms and photons in single cavities [2, 3, 4], the complex architecture of coupled cavities proposed in [10, 11, 12, 13] represents a considerable experimental challenge. In contrast, the approach described here to realize a TG gas of photons involves currently available experimental techniques. Second, we show how signatures of a strongly interacting photon gas can be detected using standard quantum optical measurements. This potentially enables many new applications and allows one to study even more exotic phenomena involving interacting particles using readily controlled photons with tunable interactions.

STRONGLY INTERACTING PHOTONS IN ONE DIMENSION: THE SYSTEM

Recently, much effort has been directed toward realizing single-mode optical waveguides where the guided photons can be tightly confined in the transverse directions to an area A_{eff} near or below the diffraction limit. Such confinement is desirable in part because it allows for a large interaction strength between single photons and nearby coupled atoms. Specific systems that have recently been explored in this context include tapered optical fibers [14], hollow-core photonic crystal fibers [15, 16], and surface plasmons on conducting nanowires [17, 18].

The propagation and interaction of photons in such a medium can be controlled by interfacing them with atoms using quantum optical techniques such as Electromagnetically Induced Transparency (EIT) [5]. In particular, our scheme relies on resonantly enhanced optical nonlinearities with low losses [19] using EIT and the creation and trapping of stationary pulses of light in the medium using spatially modulated control fields [20] (see Fig. 1a). As will be shown, the dynamical evolution of the photonic system is governed by an equation that has the form of the Nonlinear Schrödinger Equation (NLSE), where the signs and strengths of the effective mass and interaction can be controlled using external fields. Under conditions where the nonlinear interaction is large and effectively *repulsive*, the TG regime of photons can be achieved.

Specifically, we consider the propagation of counter-propagating quantum fields, characterized by operators $\hat{E}_{\pm}$, inside a single-transverse mode optical waveguide and interacting with cold atoms in the four-level configuration shown in Fig. 1b. The fields $\hat{E}_{\pm}$ couple the ground state $|a\rangle$ (in which the system is initialized) to excited state $|b\rangle$ with a strength given by g, while metastable state $|c\rangle$ and $|b\rangle$ are coupled by classical, counter-propagating control fields $\Omega_{\pm}(t)$ (we assume these fields are also guided). Here, the lambda configuration consisting of states $|a, b, c\rangle$ comprise the typical EIT setup. In particular, in the case where the quantum and classical fields propagate only in one direction, the quantum field can be dynamically and reversibly mapped into a stationary spin-wave excitation by turning the control field $\Omega(t)$ to zero adiabatically. On the other hand, as shown in [20], by creating a standing wave formation with the control fields ($\Omega_{+}(t) = \Omega_{-}(t)$), the quantum fields can be effectively stopped while simultaneously maintaining a non-zero photonic component of the excitation (see Fig. 1a). Intuitively, the standing wave pattern forms a set of reflection gratings that trap the photonic excitations through multiple scattering. The nonlinear response is introduced via an additional state $|d\rangle$ that is coupled to $|c\rangle$ by the quantum fields (for simplicity we assume that this coupling strength is also given by g). When these fields are far off resonance, this coupling results in an ac Stark shift of state $|c\rangle$ whose magnitude is proportional to the intensity of the quantum field [19]. This gives rise to an intensity-dependent refractive index, or nonlinear susceptibility, that in turn influences the evolution of the quantum fields. While similar schemes for realizing nonlinear optics in atomic media have been previously explored [21], their implementation in waveguides with tight confinement is unique because they can constitute a true one-dimensional system, and because the strong transverse localization enables large nonlinear interactions.

THE LIEB-LINIGER MODEL WITH STATIONARY PULSES OF LIGHT

Considerable theoretical literature exists discussing the connection between Maxwell's equations for a nonlinear medium in one dimension and the Lieb-Liniger Model (LLM) describing interacting massive particles [22, 23]. However, most of this work has focused on the regime of attractive interactions. Interest in this regime stems from the observation that interaction with basic two-level atomic systems leads to photon bunching, since it is easier for many photons to pass through an atom without being absorbed [24]. The main feature of the attractive regime is the formation of solitons [22]. This regime of the LLM has few quantum mechanical features and can be described by classical equations of motion. Indeed, typical optical solitons contain on the order of a million photons, and therefore a quasi-classical description is very appropriate [25]. On the other hand, the *repulsive* case is intrinsically "quantum mechanical", as one needs to keep track of correlations at the level of individual particles. Solutions based on perturbation theory or classical equations of motion break down and one needs to use non-perturbative approaches such as the Bethe ansatz solution [26, 27, 28, 29] or the Luttinger liquid formalism [30]. Thus, formation of a TG gas of photons is fundamentally a collective *many-body* effect.

We now derive an evolution equation for the fields of the system illustrated in Figure 1. Following the methods of [20, 21, 31], we define dark-state polariton operators $\Psi_{\pm}$ describing the coupled photonic and spin-wave excitations, which in the slow-light limit are given approximately by $\Psi_{\pm} = g\sqrt{2\pi n_z}\hat{E}_{\pm}/\Omega_{\pm}$, where n_z is the density of atoms coupled to the waveguide (the density is assumed to be uniform). We specialize to the case when $\Omega_{\pm}(t) = \Omega(t)$. We further assume that the quantum and control fields vary slowly in time, such that the fast-varying atomic operators can be adiabatically eliminated, while the remaining slowly-varying operators are solved in the adiabatic limit. Subsequently inserting these solutions into the Maxwell-Bloch equations describing evolution of the quantum fields yields an effective NLSE for the photon gas (see Methods),

$$i\partial_t \Psi(z,t) = -\frac{1}{2m_{\text{eff}}}\partial_z^2 \Psi(z,t) + 2\tilde{g}\Psi^{\dagger}(z,t)\Psi^2(z,t), \tag{1}$$

where

$$\Psi = \frac{(\Psi_+ + \Psi_-)}{2}, \qquad m_{\text{eff}} = -\frac{\Gamma_{1D} n_z}{4\Delta_0 v_g}, \qquad 2\tilde{g} = \frac{\Gamma_{1D} v_g}{\Delta_p}. \tag{2}$$

Here $\Gamma_{1D} = 4\pi g^2/v$ is the spontaneous emission rate of a single atom into the waveguide modes, where v is the velocity of these modes at the atomic resonance frequency in an empty waveguide, while $v_g \approx v\Omega^2/(\pi g^2 n_z)$ is the group velocity of untrapped pulses under EIT conditions. Δ_0 and Δ_p are the one-photon detunings of the fields $\hat{E}_{\pm}$ from the transitions $|a\rangle$-$|b\rangle$ and $|c\rangle$-$|d\rangle$, respectively (see Fig. 1b), and $g \sim 1/\sqrt{A_{\text{eff}}}$ is the single-photon, single-dipole interaction matrix element. In principle the full dynamics of the field will also include losses and higher-order terms, and the conditions under which such terms can be neglected are described in Methods.

Eq. (1) determines the evolution of a quantum field $\Psi(z,t)$ as derived from the Hamiltonian of the Lieb-Liniger model,

$$H = \hbar \int dz [\frac{1}{2m_{\rm eff}} \partial_z \Psi^\dagger(z) \partial_z \Psi(z) + \tilde{g} \Psi^\dagger(z) \Psi^\dagger(z) \Psi(z) \Psi(z)]. \tag{3}$$

The first term on the right describes the kinetic energy in one dimension of bosons with mass $m_{\rm eff}$, while the second term describes a contact interaction potential. The quantum field $\Psi(z,t)$ satisfies the usual equal-time bosonic commutation relations, $[\Psi(z,t), \Psi^\dagger(z',t)] = \delta(z-z')$. The behavior and properties of this system can be effectively characterized by a single dimensionless parameter

$$\gamma = \frac{m_{\rm eff}\tilde{g}}{n_{ph}} = -\frac{\Gamma_{1D}^2}{8\Delta_0\Delta_p} \frac{n_z}{n_{ph}}, \tag{4}$$

which physically corresponds to the ratio of the interaction and kinetic energies. Here n_{ph} is the density of photons at the center of the pulse. When $\gamma < 0$, the interaction with the atoms induces an effective attraction between photons. As discussed above, this is responsible, *e.g.*, for the formation of bound states (solitons) when a large number of photons are present. On the other hand, for $\gamma > 0$ the regime of effective *repulsion* between photons is realized. The special limit $\gamma \to \infty$ is called the Tonks-Girardeau (TG) regime [6, 7]. From Eq. (2), one finds that the regime of repulsion can be achieved if exactly *one* of the detuning parameters Δ_0 or Δ_p is negative. It is also clear that only the attractive regime can be reached using a two-level system, since $\Delta_0 \equiv \Delta_p$ in this situation. Finally, we note that $\gamma \propto \Gamma_{1D}^2 \propto A_{\rm eff}^{-1}$, which underscores the importance of tight mode confinement in reaching the strongly interacting regime.

One useful feature of this realization of the NLSE is that the parameters $m_{\rm eff}$ and $\tilde{g}$ can be dynamically tuned by varying different parameters of the system. Specifically, both are functions of detuning, and thus γ can be altered by changing either the control field frequencies or by externally manipulating the energies of the atomic levels. As described below, this tunability facilitates the creation of novel photonic states.

PREPARATION AND DETECTION OF STRONGLY CORRELATED PHOTON GAS

The process by which novel photonic states can be prepared and detected consists of three basic steps – loading of the pulse, controlled evolution under the NLSE, and readout of the final photonic state – each of which we now describe. During the initial loading process, a resonant optical pulse, given by, *e.g.*, a coherent state, is incident from one direction. It is injected into the waveguide at the same time that the co-propagating control field (say $\Omega_+(t)$) is turned on. During the loading procedure the counter-propagating control field $\Omega_-(t)$ is off. This describes the usual situation in EIT, where the input field becomes spatially compressed upon entering the medium and propagates with a variable group velocity $v_g \sim v\Omega_+^2(t)/(g^2 n_z)$. Once the pulse completely enters the medium, $\Omega_+(t)$ is adiabatically turned to zero, reversibly converting the photonic excitation into a pure spin-wave excitation in the atomic medium [31]. Under certain conditions this input pulse can be stored with minimal distortion relative to the initial field [31], such that all relevant properties (*e.g.*, field correlations) remain constant during the loading. Following the initial storage, both control fields are then adiabatically switched on, with $\Omega_\pm = \Omega(t)$, during which the pulse becomes trapped and evolves under Eq. (1). The parameters $m_{\rm eff}$ and $\tilde{g}$ can be changed in time during the evolution to reach the final state of interest. Once this state has been achieved, the pulse is released by turning one of the control fields (say Ω_-) off, thereby allowing the pulse to propagate undistorted until it exits the waveguide [20]. During this readout of the pulse, any spatial correlations that formed while evolving under the NLSE are directly mapped into temporal correlations (at a common point in space) in the outgoing field, which can be measured using standard quantum optical techniques.

A characteristic signature of a strongly interacting gas is the appearance of Friedel oscillations [32] in the normalized second-order correlation function, $g^{(2)}(z,z') = \langle I(z)I(z')\rangle / (\langle I(z)\rangle\langle I(z')\rangle)$, where $I(z) = \Psi^\dagger(z)\Psi(z)$ is the stationary pulse intensity prior to release. In particular, if the photonic state is close to the ground state of the LLM, $g^{(2)}(z,z')$ contains an oscillating part that behaves as $\sim \cos(2k_F(z-z'))$ (see Methods), where $k_F = \pi n_{ph}$ is the Fermi momentum in the TG limit. In the TG limit, the ground-state correlation function takes on a simple form given by Lenard's formula [33],

$$g_{TG}^{(2)}(z,z') = 1 - \left(\frac{\sin k_F(z-z')}{k_F(z-z')}\right)^2. \tag{5}$$

The $2k_F$-oscillations are a direct manifestation of "fermionization" of bosons. We note that Friedel oscillations are more than simple anti-bunching in that they indicate real crystal correlations. In particular, one cannot predict the position of an individual photon, but knowing the position of one photon, other photons are likely to follow at well-defined distances determined by the average photon density. These correlations are predicted to decay relatively slowly in space.

The usual definition of the TG regime of the LL model is given with respect to the equilibrium state. However, in our system the evolution of the initial coherent state under the NLSE inherently involves non-equilibrium quantum dynamics, and hence one must specify the conditions under which one can obtain a strongly interacting state of photons that is close to the ground state of the LLM and exhibits its characteristic features, such as Friedel oscillations. Specifically, we consider the evolution of a pulse under Eq. (1), where the atomic parameters are varied such that the effective mass $m_{\rm eff}$ is constant in time, while the interaction strength $\tilde{g}(t)$ increases exponentially. From Eq. (4), the resulting time-dependent interaction parameter can be written in the form $\gamma = \gamma_0 e^{\beta\omega_F t}$, where β is a dimensionless parameter characterizing the rate of increase, and $\omega_F{\sim}n_{ph}^2/m_{\rm eff}$ corresponds to the "Fermi energy" at the center of the pulse before expansion. We assume that $\gamma_0{\ll}1$, so that the system initially consists of non-interacting photons, and interactions are gradually switched on to reach the regime with $\gamma \gg 1$. Here we will not discuss the effect of a time-dependent mass, although it can be included using a similar analysis. We also note that the related problem involving the sudden switching of the interaction strength from zero to a large value has been studied in [34].

The non-equilibrium dynamics of the LLM model has previously been studied in the context of ultracold atoms and has focused either on changing the interaction strength in a system with uniform, constant density [35, 36], or on the expansion of particles in a system with constant interaction [37, 38]. In our system both processes take place, but in the experimentally relevant regime of a large photon number there is a separation of time scales that simplifies the analysis. We consider an initial pulse containing $N_{ph}{\sim}n_{ph}z_0$ photons with spatial extent z_0 at $t = 0$. Our discussion applies for a general pulse shape and thus we need not specify it.

There are three distinct regimes in the time evolution of the pulse: i) Interactions are weak and the photons expand freely due to dispersion; ii) Interactions begin to dominate over the kinetic energy. However, the system is still in the weakly interacting regime with $\gamma < 1$, in which case the expansion is hydrodynamic [39, 40]; iii) The system reaches the strongly interacting regime with $\gamma > 1$, and the expansion resembles that of fermionized bosons [37, 38]. A simple analysis (see Methods) shows that by the time the system reaches regime iii), the relative change in the photon density at the center of the pulse is only of the order of $\frac{1}{\beta^2 N_{ph}^2}$. Hence for $\beta N_{ph} >> 1$ one can assume that the turning on of interactions takes place at a constant density and any subsequent expansion takes place in the TG regime.

We now consider the effect of non-adiabaticity on correlation functions such as $g^{(2)}(z, z')$. By analogy with ultracold atoms, we introduce a chemical potential, which in regimes i) and ii) is given by $\mu(t) \approx \tilde{g}(t)n_{ph}$. We can approximately separate the turning on of interactions into two stages, which both take place during the regimes i) or ii). In the first stage, $\dot{\mu} > \mu^2$ and the evolution is diabatic. In the second stage, $\dot{\mu} < \mu^2$ and the evolution is essentially adiabatic. At the time t_{adiab} separating the two regimes, the interaction parameter is given by $\gamma(t_{adiab}){\sim}\beta$. The first stage can be thought of as an instantaneous projection of the wavefunction, which gives rise to a finite density of excitations characterized by an effective healing length $\xi_{neq}{\sim}(\mu(t)m_{\rm eff})^{-1/2}$ at time t_{adiab}. During the second stage, the number of excitations does not change. Hence, we find that the finite rate of change in the interaction strength leads to a finite correlation length in our system, $\xi_{neq} \sim \beta^{-1/2}n_{ph}^{-1}$. For length scales shorter than ξ_{neq}, all correlation functions are essentially the same as in the ground state, whereas for length scales longer than ξ_{neq}, correlation functions rapidly decay. To observe Friedel oscillations over length scales on the order of the inter-photon distance, for example, requires that $\beta \lesssim 1$. The argument presented above can be turned into a quantitative calculation for the correlation functions following the time dependent change in the interaction strength [36]. This analysis uses bosonization to treat the LLM and the conclusions agree with the qualitative picture presented here.

At the end of regime ii) we have a system of "fermionized" hard core photons that should exhibit Friedel oscillations. In regime iii), the pulse of "hard-core photons" expands, but such spreading does not lead to the suppression of the Friedel oscillations [37, 38]. The problem of expansion of hard-core photons starting from a general pulse shape has to be analyzed numerically. However, an explicit analytic solution is available for the case of a parabolic pulse shape. Under realistic conditions this solution, which is discussed in detail in the Methods section, yields the correlation function shown in Fig. 2.

In principle, during the evolution one must also consider the effects of photon losses, which set a maximum evolution time t_{max} and interaction parameter γ_{max} that can be achieved before a substantial fraction of the initial pulse is dissipated. As derived in the Supplementary Information (SI),

$$\gamma_{max}{\sim}\min\left(\gamma_0 \exp\left(\frac{\beta|\Delta_0|}{\Gamma}\right), \eta\beta\frac{\Gamma}{|\Delta_0|}\frac{OD}{N_{ph}}\right), \tag{6}$$

where Γ is the total spontaneous emission rate of states $|b\rangle$ and $|d\rangle$ (assumed to be equal for simplicity), which includes the emission rate into the waveguide modes (Γ_{1D}) as well as emission into non-guided modes (*e.g.*, into free space). We have also defined a single-atom cooperativity $\eta = \Gamma_{1D}/\Gamma$ ($\eta \leq 1$) which describes the rate of emission into the waveguide compared to the total emission, and defined the optical depth of the medium, $OD = \eta z_0 n_z$. We note that γ_{max} can be improved by increasing the optical depth or cooperativity of the system, and optimized by adjusting the detuning $|\Delta_0|$. The optimal values of γ_{max}, as functions of optical depth and cooperativity, are plotted in Fig. 3, for parameters $\beta = 1, \gamma_0 = 0.1$, and $N_{ph} = 10$. One sees that with realistic values of $OD \sim 2000$ and $\eta \sim 0.2$, for example, an interaction parameter of $\gamma_{max} \sim 10$ is possible. While photon losses limit the maximum evolution time, somewhat surprisingly, the nonlinear losses may also help in bringing the system closer to the ground state of the LLM model. Specifically, these losses predominantly remove states in which two photons are close to each other, which correspond to high energy states of the LLM. Deep in the TG regime we can estimate the time it takes for the system to lose the high energy states, $t_{en}^{-1} \approx \frac{\Gamma}{\Delta_p} \tilde{g} n_{ph}$. On the other hand, the photon loss rate is $t_{los}^{-1} \approx \frac{\Gamma}{\Delta_p} \omega_F$. Thus $t_{en}/t_{los} \approx \gamma^{-1}$ and for large γ there is a sufficient time window for the high-energy states to decay before too many photons are lost.

OUTLOOK

The above analysis indicates that strongly correlated states of photons can be controllably prepared and observed in one-dimensional waveguides. These techniques are made possible through strong coupling between the photons and nearby atoms and the use of quantum optical techniques such as EIT, which allow the system to be widely tunable. Such photonic states should find numerous applications in various areas of physics. Crystal correlations that arise in the fermionized state make it a promising candidate for applications in metrology and quantum information. In particular, TG states feature strongly suppressed photon number fluctuations within a given detection interval. Such states therefore could be used as an input for sub-shot noise interferometers [41, 42], or in extension to schemes for quantum computing [43] or quantum cryptography [44] that rely on single photons. Another exciting direction is quantum simulation of matter Hamiltonians using optical systems. In the discussion so far, we have considered photons with only one polarization. Including photons of different polarizations should be equivalent to adding a spin degree of freedom to effective matter Hamiltonians. This opens up exciting prospects for exploring spin charge separation (see, *e.g.*, [45]) and modelling exotic spin systems. It is also interesting to note that the level structure of the atoms comprising the medium can vary considerably. This fact can be used for the study of strongly-correlated systems with non-Abelian symmetry, similar to the ones realized in multi-channel Kondo models and quantum chromodynamics. Possible phases and phase transitions in these models are difficult, if possible at all, to realize in matter systems. Furthermore, it would be interesting to consider a situation where interactions between the cold atoms create non-trivial correlations [46] and their effect on the resulting photonic states. Using light to simulate matter Hamiltonians will give a new meaning to the old idea of the particle-wave duality.

METHODS

Derivation of NLSE for photons

The Hamiltonian corresponding to the system described in Fig. 1 is given in a rotating frame by

$$\begin{aligned} H = -\hbar n_z \int dz[\Delta_0 \sigma_{bb} + \Delta_p \sigma_{dd} + g\sqrt{2\pi}((\sigma_{ba} + \sigma_{dc})(\hat{E}_+ e^{ik_0 z} + \hat{E}_- e^{-ik_0 z}) + h.c.) \\ +((\Omega_+(t) e^{ik_c z} + \Omega_-(t) e^{-ik_c z})\sigma_{bc} + h.c.)], \end{aligned} \tag{7}$$

where $\hat{E}_\pm \equiv \hat{E}_\pm(z,t)$ are slowly-varying operators describing the quantum fields, and $\sigma_{ij} \equiv \sigma_{ij}(z,t)$ are collective, continuous operators describing the average of $|i\rangle\langle j|$ over atoms in a small but macroscopic region around z. For simplicity, we have assumed equal transition matrix elements $g_{ba} = g_{dc} = g$ between the quantum fields $\hat{E}_\pm$ and the transitions $|a\rangle$-$|b\rangle$ and $|c\rangle$-$|d\rangle$, where $g_{ij} \sim \langle i|r|j\rangle \sqrt{\omega_{ij}/\hbar\epsilon_0 A_{\text{eff}}}$. Note that we have also included a one-photon detuning Δ_0 between the quantum fields and transition $|a\rangle$-$|b\rangle$ (while maintaining two-photon resonance), whose purpose is to provide a group velocity dispersion or "effective mass" term in the field evolution equations. Defining slowly varying operators $\sigma_{ab} = \sigma_{ab,+} e^{ik_0 z} + \sigma_{ab,-} e^{-ik_0 z}$ and $\sigma_{cd} = \sigma_{cd,+} e^{ik_0 z} + \sigma_{cd,-} e^{-ik_0 z}$, the Maxwell-Bloch equations describing evolution of the fields under H are given by

$$\left(\frac{1}{v}\frac{\partial}{\partial t} \pm \frac{\partial}{\partial z}\right) \hat{E}_{\pm}(z,t) = \frac{\sqrt{2\pi} i g n_z}{v} \left(\sigma_{ab,\pm}(z,t) + \sigma_{cd,\pm}(z,t)\right), \tag{8}$$

while the usual Langevin-Bloch equations describing evolution of σ_{ij} can be derived following the methods of [20, 21, 31]. Following these references, we define polariton operators $\Psi_{\pm}$ to describe the collective excitations of field and spin-wave coherence σ_{ac} that result from coupling with the control fields, which in the relevant limit that the excitations are mostly in spin-wave form are given by $\Psi_{\pm} = g\sqrt{2\pi n_z}\hat{E}_{\pm}/\Omega_{\pm}$. To proceed further, we adiabatically eliminate the Langevin-Bloch equations for the fast-decaying atomic operators (*e.g.*, σ_{ab} and σ_{cd}), and slowly-varying operators are solved in terms of $\Psi_{\pm}$, discarding higher time derivatives in the slowly-varying limit. Plugging these results back into Eq. (8), and specializing to the case where $\Omega_{\pm}(t) = \Omega$, we obtain evolution equations for the polaritons alone,

$$\begin{aligned} \frac{1}{v}\partial_t \Psi + \partial_z A &= -\frac{1}{v_g}\partial_t \Psi - \frac{2\pi i g^2}{v(2\Delta_p + i\Gamma)}\left(2\Psi^\dagger \Psi + A^\dagger A\right)\Psi + \text{noise}, & (9)\\ \frac{1}{v}\partial_t A + \partial_z \Psi &= -\frac{4\pi g^2 n_z}{v(\Gamma - 2i\Delta_0)} A - \frac{2\pi i g^2}{v(2\Delta_p + i\Gamma)}\Psi^\dagger \Psi A + \text{noise}. & (10)\end{aligned}$$

Here we have defined the symmetric and anti-symmetric combinations $\Psi = (\Psi_+ + \Psi_-)/2$ and $A = (\Psi_+ - \Psi_-)/2$, and a group velocity $v_g \approx v\Omega^2/(\pi g^2 n_z)$ under which the pulses would propagate were they not trapped. The total spontaneous emission rates Γ (which include decay into channels other than the guided fiber modes) from states $|b\rangle, |d\rangle$ are assumed to be identical for simplicity. We note that there are also noise operators, which are associated with the dissipative terms in the equations above. Because we are primarily interested in the regime where losses are not significant, the specific form of these operators is not important here. With sufficient optical depth, A can be adiabatically eliminated, $A \approx (2i\Delta_0 - \Gamma)v(\partial_z \Psi)/(4\pi g^2 n_z)$, where we have assumed that the nonlinear contribution $\sim \Psi^\dagger \Psi A$ is small. Physically, this result corresponds to a pulse matching phenomenon [47] between the quantum and control fields, whereby any imbalance between Ψ_+ and Ψ_- rapidly goes to zero. Substituting the expression for A back into Eq. (9), and considering the relevant case where $v_g \ll v$ yields the NLSE with complex effective mass and two-body interaction strength,

$$i\partial_t \Psi = \frac{(2\Delta_0 + i\Gamma)v_g v}{4\pi g^2 n_z}\partial_z^2 \Psi + \frac{4\pi g^2 v_g}{v(\Delta_p + i\Gamma/2)}\Psi^\dagger \Psi^2 + \text{noise}. \tag{11}$$

Identifying $\Gamma_{1D} = 4\pi g^2/v$ and ignoring the loss terms reproduces the ideal NLSE given in Eq. (1).

We now consider carefully the limits under which Eq. (1) well approximates the complete dynamics of the field. First, one requires that the ac Stark shift of $|c\rangle$ due to the nonlinear interaction fits within the frequency range where EIT is efficient (*i.e.*, within the transparency window), which is conservatively satisfied when $n_{ph}/n_z \ll |\Delta_p|/|\Gamma - 2i\Delta_0|$. In addition, requiring that higher-order derivatives of the field be negligible compared to those appearing in Eq. (1) places a restriction on the maximum wavevector k_{max} of the spin-wave excitation. In the TG regime, for example, $k_{max} \sim n_{ph}$ and one consequently finds that $n_{ph}/n_z \ll \Gamma_{1D}/|2\Delta_0 + i\Gamma|$. Finally, as discussed further in SI, one must also ensure that the loss terms in Eq. (11) do not cause the dissipation of too many photons, which sets a maximum allowed evolution time t_{max} for the system.

Density-density correlations in one-dimensional system of bosons

Evaluation of the density-density correlation function in the ground state is challenging even though the Hamiltonian in Eq. (3) is exactly solvable. However, in the regime of interest where γ is large, one can obtain an analytic expression [27] (we assume that translational invariance is present and therefore $g^{(2)}(z_1, t_1; z_2, t_2) = g^{(2)}(z_1 - z_2 = \Delta z, t_1 - t_2 = \Delta t)$),

$$g^{(2)}(\Delta z, \Delta t) = 1 + \frac{K}{4\pi^2 n_{ph}^2}\int_{|q_1| > \pi n_{ph}} \int_{|q_2| < \pi n_{ph}} e^{it(q_1^2 - q_2^2)} \cos[(q_1 - q_2)z\sqrt{K}][1 + \frac{q_1 - q_2}{\pi \tilde{g}} \int_{-\pi n_{ph}}^{\pi n_{ph}} (\frac{1}{q_3 - q_1} - \frac{1}{q_3 - q_2})], \tag{12}$$

where $K = 1 + 4/\gamma$. Note that $g^{(2)}$ decays as t^{-1} for a range of $t > 0$.

For arbitrary interaction strength one can use the exact solution to numerically evaluate $g^{(2)}$ [27, 28, 29]. On the other hand this numerical solution [28, 29] as well as a number of other arguments [30, 48] suggests that an effective description of a one-dimensional gas of bosons, the Luttinger liquid theory, provides very good long-distance, long-time behavior. Using this theory, one can demonstrate that the density-density correlation function in the ground state exhibits a power-law decay of correlations and $2k_F$ Friedel oscillations,

$$g^{(2)}(\Delta z, \Delta t) = 1 + \frac{K}{2\pi^2 n_{ph}^2} \frac{(\Delta z)^2 - (v_g \Delta t)^2}{[(\Delta z)^2 + (v_g \Delta t)^2]^2} + \frac{B \cos(2k_F \Delta z)}{n_{ph}^2 |\Delta z + i v_g \Delta t|^{2K}} \tag{13}$$

where B is a non-universal constant. The interaction parameter K, or Luttinger parameter [30, 48], can be numerically extracted from the exact solution. In the limit of strong interactions, $K = 1 + 4/\gamma$ and tends to 1 in the TG regime. Here $k_F = \pi n_{ph}$ is an emergent *Fermi* momentum.

In the case of sudden switch on of the interaction, one can use the completeness of the Bethe-Ansatz wave functions basis and expand the initial state over this basis. Since the matrix elements of the density operator in the Bethe states are known [49], computation of the density-density correlation function starting from an arbitrary initial state can in principle be performed [34].

Expansion of the pulse

We consider the expansion of the optical pulse during stages i) and ii) introduced in the Section "Preparation and detection of strongly correlated photon gas". In regime i), the interaction energy of particles can be neglected in comparison with the kinetic energy as long as $\tilde{g}(t) n_{ph}$ is smaller than the kinetic energy $1/m_{\text{eff}} z_0^2$. The time t_1 at which these energies become comparable satisfies $t \propto -\log(N_{ph}^2 \gamma_0)$, and thus if one chooses parameters such that $N_{ph}^2 \gamma_0 > 1$ free expansion can be ignored (for large photon number one can simultaneously satisfy $\gamma_0 \ll 1$ such that the system is initially non-interacting). Regime ii), which is valid until $\gamma(t = t_c) = 1$, can be analyzed using the usual hydrodynamic equations (see, *e.g.*, Refs. [39, 40]). From the equation of motion for the flow velocity, we find $\dot{v}(t) \sim \frac{n_{ph}}{m_{\text{eff}} z_0} g(t)$, and from the conservation of particle number, $\dot{n}(t) \sim \frac{n_{ph}}{z_0} v(t)$. Assuming that the change in density at the center of the pulse is small, these equations can be integrated to yield a relative change of density $\Delta n_{ph}/n_{ph} \sim 1/\beta^2 N_{ph}^2$.

Next we consider the expansion in the strongly interacting regime. Recent work [37, 38] demonstrated that spreading of a pulse of hard core bosons enhances the "fermionic" character of the wavefunction [37]. While generally this problem requires numerical simulations, the solution turns out to be extremely simple for an initial pulse density of the form $n_{ph}(z) = n_0(1 - z^2/z_0^2)^{1/2}$, which corresponds to hard core bosons released from a parabolic potential [38]. In this case the structure of the density correlations is preserved and there is only a rescaling of length scales [38]. An explicit calculation of $g^{(2)}$ for this system is shown in Fig. 2. Another signature of fermionization of an expanding pulse of hard core bosons can be observed in the momentum distribution function $n(k)$ (density at wavevector k), corresponding to the Fourier transform of the first order correlation function $g^{(1)}(z, z') = \langle \psi(z) \psi^\dagger(z') \rangle$. After sufficiently long expansion it approaches a Fermi distribution [37, 38]. We emphasize that the qualitative features of our results remain valid for various shapes of the initial pulse, including Gaussian and parabolic pulses, although numerical analysis is needed to obtain precise answers.

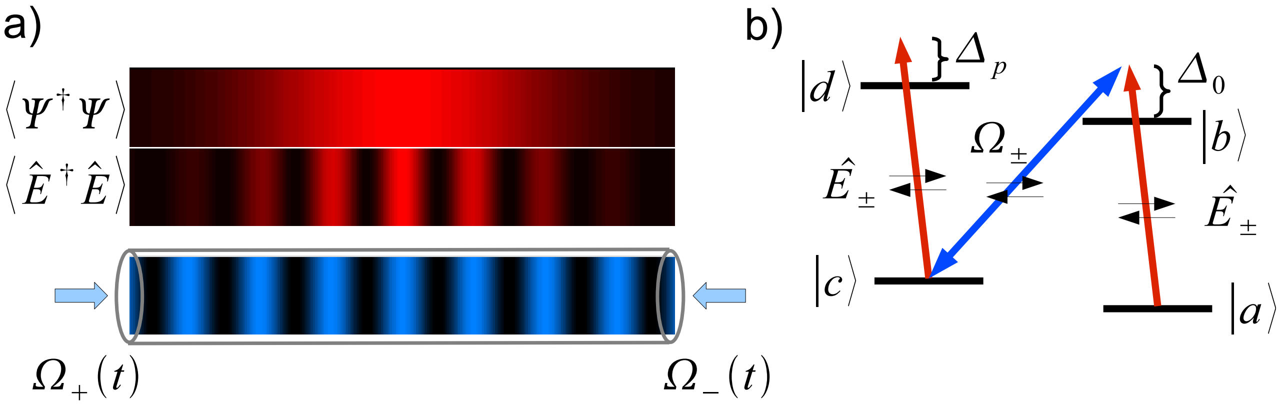

FIG. 1: **Illustration of fields and atoms comprising the system** a) Schematic of fields inside the waveguide, whose axis of propagation corresponds to the horizontal axis. The control beams $\Omega_{\pm}(t)$ (shown in blue) create a standing wave inside the waveguide, which forms a Bragg grating that traps a quantum optical field inside the medium (intensity $\langle\hat{E}^{\dagger}\hat{E}\rangle$ shown in red). The optical field couples to spin-wave excitations in the medium, resulting in collective polariton excitations whose density $\langle\Psi^{\dagger}\Psi\rangle$ is also plotted. b) Schematic of the four-level atomic configuration and coupling between levels and fields used in our system.

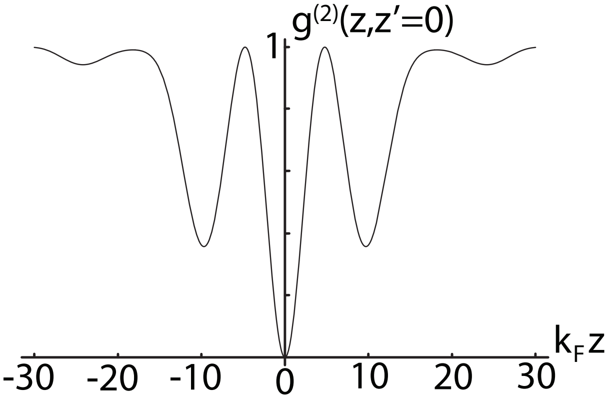

FIG. 2: **Density-density correlation function** $g^{(2)}(z, z' = 0)$ for an expanding Tonks-Girardeau gas of photons with initial density profile $n_{ph}(z) = n_0(1 - z^2/z_0^2)^{1/2}$. This expansion is equivalent to the problem of a TG gas released from an initial parabolic confining potential. $z' = 0$ denotes the center of the pulse, and distances are indicated in units of k_F^{-1}. The density-density correlation function shown here is for a system of $N_{ph} = 10$ photons, $z_0 \approx 5k_F^{-1}$, and at a time $t = 10\omega_F^{-1}$ following the initial release.

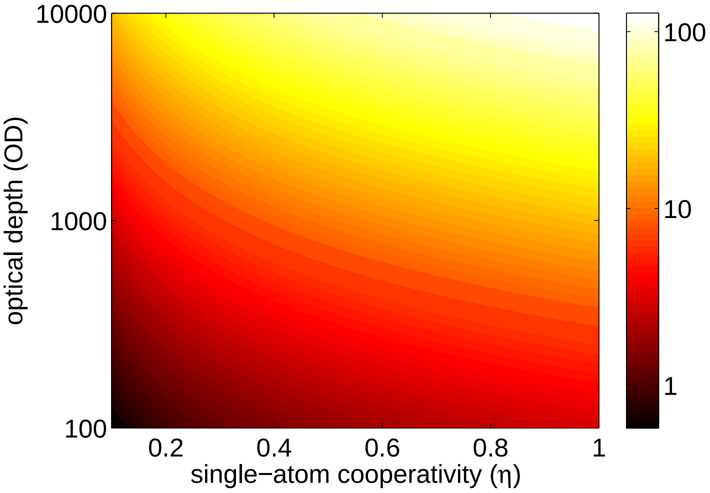

FIG. 3: **Maximum interaction parameter** γ_{max} as functions of optical depth and single-atom cooperativity, optimized over the detuning Δ_0. γ_{max} is plotted for fixed values of $\beta = 1$, $\gamma_0 = 0.1$, and $N_{ph} = 10$. It is evident that the TG regime for photons can be approached by increasing either the cooperativity or optical depth.
